Abstract

In this paper we consider the problem of identifying and classifying discourse coherence relations. We report initial results over the recently released Discourse Graphbank (Wolf and Gibson, 2005). Our approach considers, and determines the contributions of, a variety of syntactic and lexical-semantic features. We achieve 81% accuracy on the task of discourse relation type classification and 70% accuracy on relation identification.

1 Introduction

The area of modeling discourse has arguably seen less success than other areas in NLP. Contributing to this is the fact that no consensus has been reached on the inventory of discourse relations nor on the types of formal restrictions placed on discourse structure. Furthermore, modeling discourse structure requires access to considerable prior linguistic analysis including syntax, lexical and compositional semantics, as well as the resolution of entity and event-level anaphora, all of which are non-trivial problems themselves.

Discourse processing has been used in many text processing applications, most notably text summarization and compression, text generation, and dialogue understanding. However, it is also important for general text understanding, including applications such as information extraction and question answering.

Recently, Wolf and Gibson (2005) have proposed a graph-based approach to representing informational discourse relations. They demonstrate that tree representations are inadequate for modeling coherence relations, and show that many discourse segments have multiple parents (incoming directed relations) and many of the relations introduce crossing dependencies – both of which preclude tree representations. Their annotation of 135 articles has been released as the GraphBank corpus.

In this paper, we provide initial results for the following tasks: (1) automatically classifying the type of discourse coherence relation; and (2) identifying whether any discourse relation exists on two text segments. The experiments we report are based on the annotated data in the Discourse Graphbank, where we assume that the discourse units have already been identified.

In contrast to a highly structured, compositional approach to discourse parsing, we explore a simple, flat, feature-based methodology. Such an approach has the advantage of easily accommodating many knowledge sources. This type of detailed feature analysis can serve to inform or augment more structured, compositional approaches to discourse such as those based on Segmented Discourse Representation Theory (SDRT) (Asher and Lascarides, 2003) or the approach taken with the D-LTAG system (Forbes et al., 2001).

Using a comprehensive set of linguistic features as input to a Maximum Entropy classifier, we achieve 81% accuracy on classifying the correct type of discourse coherence relation between two segments.

The relations they define roughly follow Hobbs (1985).
2 Previous Work

In the past few years, the tasks of discourse segmentation and parsing have been tackled from different perspectives and within different frameworks. Within Rhetorical Structure Theory (RST), Soricut and Marcu (2003) have developed two probabilistic models for identifying clausal elementary discourse units and generating discourse trees at the sentence level. These are built using lexical and syntactic information obtained from mapping the discourse-annotated sentences in the RST Corpus (Carlson et al., 2003) to their corresponding syntactic trees in the Penn Treebank.

Within SDRT, Balridge and Lascarides (2005b) also take a data-driven approach to the tasks of segmentation and identification of discourse relations. They create a probabilistic discourse parser based on dialogues from the Redwoods Treebank, annotated with SDRT rhetorical relations (Balridge and Lascarides, 2005a). The parser is grounded on headed tree representations and dialogue-based features, such as turn-taking and domain specific goals.

In the Penn Discourse TreeBank (PDTB) (Webber et al., 2005), the identification of discourse structure is approached independently of any linguistic theory by using discourse connectives rather than abstract rhetorical relations. PDTB assumes that connectives are binary discourse-level predicates conveying a semantic relationship between two abstract object-denoting arguments. The set of semantic relationships can be established at different levels of granularity, depending on the application. Miltsakaki, et al. (2005) propose a first step at disambiguating the sense of a small subset of connectives (since, while, and when) at the paragraph level. They aim at distinguishing between the temporal, causal, and contrastive use of the connective, by means of syntactic features derived from the Penn Treebank and a MaxEnt model.

3 Graphbank

3.1 Coherence Relations

For annotating the discourse relations in text, Wolf and Gibson (2005) assume a clause-unit-based definition of a discourse segment. They define four broad classes of coherence relations:

1. **Resemblance**: similarity (par), contrast (contr), example (exmp), generalization (gen), elaboration (elab);
2. **Cause-effect**: explanation (ce), violated expectation (expv), condition (cond);
3. **Temporal (temp)**: essentially narration;
4. **Attribution (attr)**: reporting and evidential contexts.

The textual evidence contributing to identifying the various resemblance relations is heterogeneous at best, where, for example, similarity and contrast are associated with specific syntactic constructions and devices. For each relation type, there are well-known lexical and phrasal cues:

1. a. **similarity**: and;
   b. **contrast**: by contrast, but;
   c. **example**: for example;
   d. **elaboration**: also, furthermore, in addition, note that;
   e. **generalization**: in general.

However, just as often, the relation is encoded through lexical coherence, via semantic association, sub/supertyping, and accommodation strategies (Asher and Lascarides, 2003).

The cause-effect relations include conventional causation and explanation relations (captured as the label ce), such as (3) below:

3. **cause**: SEG1: crash-landed in New Hope, Ga.,
   **effect**: SEG2: and injuring 23 others.

It also includes conditionals and violated expectations, such as (4).

4. **cause**: SEG1: an Eastern Airlines Lockheed L-1011 en route from Miami to the Bahamas lost all three of its engines,
   **effect**: SEG2: and land safely back in Miami.

The two last coherence relations annotated in Graphbank are temporal (temp) and attribution (attr) relations. The first corresponds generally to the occasion (Hobbs, 1985) or narration (Asher and Lascarides, 2003) relation, while the latter is a general annotation over attribution of source.2

3.2 Discussion

The difficulty of annotating coherence relations consistently has been previously discussed in the literature. In GraphBank, as in any corpus, there are inconsistencies that must

---

2 There is one non-rhetorical relation, same, which identifies discontiguous segments.
be accommodated for learning purposes. As perhaps expected, annotation of attribution and temporal sequence relations was consistent if not entirely complete. The most serious concern we had from working with the corpus derives from the conflation of diverse and semantically contradictory relations among the cause-effect annotations. For canonical causation pairs (and their violations) such as those above, (3) and (4), the annotation was expectedly consistent and semantically appropriate. Problems arise, however when examining the treatment of purpose clauses and rationale clauses. These are annotated, according to the guidelines, as cause-effect pairings. Consider (5) below.

(5) **cause:** SEG1: to upgrade lab equipment in 1987.  
**effect:** SEG2: The university spent $30,000

This is both counter-intuitive and temporally false. The rationale clause is annotated as the cause, and the matrix sentence as the effect. Things are even worse with purpose clause annotation. Consider the following example discourse.3

(6) John pushed the door to open it, but it was locked.

This would have the following annotation in GraphBank:

(7) **cause:** to open it  
**effect:** John pushed the door.

The guideline reflects the appropriate intuition that the intention expressed in the purpose or rationale clause must precede the implementation of the action carried out in the matrix sentence. In effect, this would be something like

(8) \texttt{[INTENTION TO SEG1] CAUSES SEG2}

The problem here is that the cause-effect relation conflates real event-causation with telos-directed explanations, that is, action directed towards a goal by virtue of an intention. Given that these are semantically disjoint relations, which are furthermore triggered by distinct grammatical constructions, we believe this conflation should be undone and characterized as two separate coherence relations. If the relations just discussed were annotated as telic-causation, the features encoded for subsequent training of a machine learning algorithm could benefit from distinct syntactic environments. We would like to automatically generate temporal orderings from cause-effect relations from the events directly annotated in the text. Splitting these classes would preserve the soundness of such a procedure, while keeping them lumped generates inconsistencies.

4 Data Preparation and Knowledge Sources

In this section we describe the various linguistic processing components used for classification and identification of Graphbank discourse relations.

4.1 Pre-Processing

We performed tokenization, sentence tagging, part-of-speech tagging, and shallow syntactic parsing (chunking) over the 135 Graphbank documents. Part-of-speech tagging and shallow parsing were carried out using the Carafe implementation of Conditional Random Fields for NLP (Wellner and Vilain, 2006) trained on various standard corpora. In addition, full sentence parses were obtained using the RASP parser (Briscoe and Carroll, 2002). Grammatical relations derived from a single top-ranked tree for each sentence (headword, modifier, and relation type) were used for feature construction.

4.2 Modal Parsing and Temporal Ordering of Events

We performed both modal parsing and temporal parsing over events. Identification of events was performed using EvITA (Saurí et al., 2006), an open-domain event tagger developed under the TARSQI research framework (Verhagen et al., 2005). EvITA locates and tags all event-referring expressions in the input text that can be temporally ordered. In addition, it identifies those grammatical features implicated in temporal and modal information of events; namely, tense, aspect, polarity, modality, as well as the event class. Event annotation follows version 1.2.1 of the TimeML specifications.4

---

3This specific example was brought to our attention by Alex Lascarides (p.c).

4See http://www.timeml.org.
Modal parsing in the form of identifying subordinating verb relations and their type was performed using SlinkET (Saurí et al., 2006), another component of the TARSQI framework. SlinkET identifies subordination constructions introducing modality information in text; essentially, infinitival and that-clauses embedded by factive predicates (regret), reporting predicates (say), and predicates referring to events of attempting (try), volition (want), command (order), among others. SlinkET annotates these subordination contexts and classifies them according to the modality information introduced by the relation between the embedding and embedded predicates, which can be of any of the following types:

- **factive**: The embedded event is presupposed or entailed as true (e.g., John managed to leave the party).
- **counter-factive**: The embedded event is presupposed as entailed as false (e.g., John was unable to leave the party).
- **evidential**: The subordination is introduced by a reporting or perception event (e.g., Mary saw/told that John left the party).
- **negative evidential**: The subordination is a reporting event conveying negative polarity (e.g., Mary denied that John left the party).
- **modal**: The subordination creates an intensional context (e.g., John wanted to leave the party).

Temporal orderings between events were identified using a Maximum Entropy classifier trained on the TimeBank 1.2 and Opinion 1.0a corpora. These corpora provide annotated events along with temporal links between events. The link types included: before (e₁ occurs before e₂), includes (e₂ occurs sometime during e₁), simultaneous (e₁ occurs over the same interval as e₂), begins (e₁ begins at the same time as e₂), ends (e₁ ends at the same time as e₂).

4.3 Lexical Semantic Typing and Coherence

Lexical semantic types as well as a measure of lexical similarity or coherence between words in two discourse segments would appear to be useful for assigning an appropriate discourse relationship. Resemblance relations, in particular, require similar entities to be involved and lexical similarity here serves as an approximation to definite nominal coreference. Identification of lexical relationships between words across segments appears especially useful for cause-effect relations. In example (3) above, determining a (potential) cause-effect relationship between crash and injury is necessary to identify the discourse relation.

4.3.1 Corpus-based Lexical Similarity

Lexical similarity was computed using the Word Sketch Engine (WSE) (Kilgarrif et al., 2004) similarity metric applied over British National Corpus. The WSE similarity metric implements the word similarity measure based on grammatical relations as defined in (Lin, 1998) with minor modifications.

4.3.2 The Brandeis Semantic Ontology

As a second source of lexical coherence, we used the Brandeis Semantic Ontology or BSO (Pustejovsky et al., 2006). The BSO is a lexically-based ontology in the Generative Lexicon tradition (Pustejovsky, 2001; Pustejovsky, 1995). It focuses on contextualizing the meanings of words and does this by a rich system of types and qualia structures. For example, if one were to look up the phrase RED WINE in the BSO, one would find its type is WINE and its type’s type is ALCOHOLIC BEVERAGE. The BSO contains ontological qualia information (shown below). Using the BSO,

```plaintext
<table>
<thead>
<tr>
<th>wine</th>
</tr>
</thead>
<tbody>
<tr>
<td>constitutive = Alkol</td>
</tr>
<tr>
<td>has element = Alcohol</td>
</tr>
<tr>
<td>made of = Grapes</td>
</tr>
<tr>
<td>indirect telic = drink activity</td>
</tr>
<tr>
<td>indirect agentive = make alcoholic beverage</td>
</tr>
</tbody>
</table>
```

one is able to find out where in the ontological type system WINE is located, what RED WINE’s lexical neighbors are, and its full set of part of speech and grammatical attributes. Other words have a different configuration of annotated attributes depending on the type of the word.

We used the BSO typing information to semantically tag individual words in order to compute lexical paths between word pairs. Such lexical associations are invoked when constructing cause-effect relations and other implicatures (e.g., between crash and injure in Example 3).
The type system paths provide a measure of the connectedness between words. For every pair of head words in a GraphBank document, the shortest path between the two words within the BSO is computed. Currently, this metric only uses the type system relations (i.e., inheritance) but preliminary tests show that including qualia relations as connections is promising. We also computed the earliest common ancestor of the two words. These metrics are calculated for every possible sense of the word within the BSO.

The use of the BSO is advantageous compared to other frameworks such as Wordnet because it focuses on the connection between words and their semantic relationship to other items. These connections are captured in the qualia information and the type system. In Wordnet, qualia-like information is only present in the glosses, and they do not provide a definite semantic path between any two lexical items. Although synonymous in some ways, synset members often behave differently in many situations, grammatical or otherwise.

5 Classification Methodology

This section describes in detail how we constructed features from the various knowledge sources described above and how they were encoded in a Maximum Entropy model.

5.1 Maximum Entropy Classification

For our experiments of classifying relation types, we used a Maximum Entropy classifier\(^5\) in order to assign labels to each pair of discourse segments connected by some relation. For each instance (i.e. pair of segments) the classifier makes its decision based on a set of features. Each feature can query some arbitrary property of the two segments, possibly taking into account external information or knowledge sources. For example, a feature could query whether the two segments are adjacent to each other, whether one segment contains a discourse connective, whether they both share a particular word, whether a particular syntactic construction or lexical association is present, etc. We make strong use of this ability to include very many, highly interdependent features\(^6\) in our experiments. Besides binary-valued features, feature values can be real-valued and thus capture frequencies, similarity values, or other scalar quantities.

5.2 Feature Classes

We grouped the features together into various feature classes based roughly on the knowledge source from which they were derived. Table 1 describes the various feature classes in detail and provides some actual example features from each class for the segment pair described in Example 5 in Section 3.2.

6 Experiments and Results

In this section we provide the results of a set of experiments focused on the task of discourse relation classification. We also report initial results on relation identification with the same set of features as used for classification.

6.1 Discourse Relation Classification

The task of discourse relation classification involves assigning the correct label to a pair of discourse segments.\(^7\) The pair of segments to assign a relation to is provided (from the annotated data). In addition, we assume, for asymmetric links, that the nucleus and satellite are provided (i.e., the direction of the relation). For the elaboration relations, we ignored the annotated subtypes (person, time, location, etc.). Experiments were carried out on the full set of relation types as well as the simpler set of coarse-grained relation categories described in Section 3.1.

The GraphBank contains a total of 8755 annotated coherence relations.\(^8\) For all the experiments in this paper, we used 8-fold cross-validation with 12.5% of the data used for testing and the remainder used for training for each fold. Accuracy numbers reported are the average accuracies over the 8 folds. Variance was generally low with a standard deviation typically in the range of 1.5 to 2.0. We

---

\(^5\)We use the Maximum Entropy classifier included with Carafe available at http://sourceforge.net/projects/carafe

\(^6\)The total maximum number of features occurring in our experiments is roughly 120,000.

\(^7\)Each segment may in fact consist of a sequence of segments. We will, however, use the term segment loosely to refer to segments or segment sequences.

\(^8\)All documents are doubly annotated; we used the annotator\(^1\) annotations,
note here also that the interannotator agreement between the two GraphBank annotators was 94.6% for relations when they agreed on the presence of a relation. The majority class baseline (i.e., the accuracy achieved by calling all relations elaboration) is 45.7% (and 66.57% with the collapsed categories). These are the upper and lower bounds against which these results should be basel.

To ascertain the utility of each of the various feature classes, we considered each feature class independently by using only features from a single class in addition to the Proximity feature class which serve as a baseline. Table 2 illustrates the result of this experiment.

We performed a second set of experiments shown in Table 3 that is essentially the converse of the previous batch. We take the union of all the feature classes and perform ablation experiments by removing one feature class at a time.

### 6.2 Analysis

From the ablation results, it is clear that overall performance is most impacted by the cue-
word features (C) and proximity (P). Syntax and SlinkET also have high impact improving accuracy by roughly 10 and 9 percent respectively as shown in Table 2. From the ablation results in Table 3, it is clear that the utility of most of the individual features classes is lessened when all the other feature classes are taken into account. This indicates that multiple feature classes are responsible for providing evidence any given discourse relations. Removing a single feature class degrades performance, but only slightly, as the others can compensate.

Overall precision, recall and F-measure results for each of the different link types using the set of all feature classes are shown in Table 4 with the corresponding confusion matrix in Table A.1. Performance correlates roughly with the frequency of the various relation types. We might therefore expect some improvement in performance with more annotated data for those relations with low frequency in the GraphBank.

6.3 Coherence Relation Identification

The task of identifying the presence of a relation is complicated by the fact that we must consider all \( \binom{n}{2} \) potential relations where \( n \) is the number of segments. This presents a troublesome, highly-skewed binary classification problem with a high proportion of negative instances. Furthermore, some of the relations, particularly the resemblance relations, are transitive in nature (e.g., \( \text{parallel}(s_i, s_j) \land \text{parallel}(s_j, s_k) \rightarrow \text{parallel}(s_i, s_k) \)). However, these transitive links are not provided in the GraphBank annotation - such segment pairs will therefore be presented incorrectly as negative instances to the learner, making this approach infeasible. An initial experiment considering all segment pairs, in fact, resulted in performance only slightly above the majority class baseline.

Instead, we consider the task of identifying the presence of discourse relations between segments within the same sentence. Using the same set of all features used for relation classification, performance is at 70.04\% accuracy. Simultaneous identification and classification resulted in an accuracy of 64.53\%. For both tasks the baseline accuracy was 58\%.

6.4 Modeling Inter-relation Dependencies

Casting the problem as a standard classification problem where each instance is classified independently, as we have done, is a potential drawback. In order to gain insight into how collective, dependent modeling might help, we introduced additional features that model such dependencies: For a pair of discourse segments, \( s_i \) and \( s_j \), to classify the relation between, we included features based on the other relations involved with the two segments (from the gold standard annotations): \( \{ R(s_i, s_k) \mid k \neq j \} \) and \( \{ R(s_j, s_l) \mid l \neq i \} \). Adding these features improved classification accuracy to 82.3\%. This improvement is fairly significant (a 6.3\% reduction in error) given that this dependency information is only encoded weakly as features and not in the form of model constraints.

7 Discussion and Future Work

We view the accuracy of 81\% on coherence relation classification as a positive result, though room for improvement clearly remains. An examination of the errors indicates that many of the remaining problems require making complex lexical associations, the establishment of entity and event anaphoric links and, in some cases, the exploitation of complex world-knowledge. While important lexical connections can be gleaned from the BSO, we hypothesize that the current lack of word sense disambiguation serves to lessen its utility since lexical paths between all word sense of two words are currently used. Additional feature engineering, particularly the crafting of more specific conjunctions of existing features is an-
other avenue to explore further - as are automatic feature selection methods.

Different types of relations clearly benefit from different feature types. For example, resemblance relations require similar entities and/or events, indicating a need for robust anaphora resolution, while cause-effect class relations require richer lexical and world knowledge. One promising approach is a pipeline where an initial classifier assigns a coarse-grained category, followed by separately engineered classifiers designed to model the finer-grained distinctions.

An important area of future work involves incorporating additional structure in two places. First, as the experiment discussed in Section 6.4 shows, classifying discourse relations collectively shows potential for improved performance. Secondly, we believe that the tasks of: 1) identifying which segments are related and 2) identifying the discourse segments themselves are probably best approached by a parsing model of discourse. This view is broadly sympathetic with the approach in (Miltsakaki et al., 2005).

We furthermore believe an extension to the GraphBank annotation scheme, with some minor changes as we advocate in Section 3.2, layered on top of the PDTB would, in our view, serve as an interesting resource and model for informational discourse.
